ABSTRACT

Background & aims: Cholangiopathies are chronic liver diseases in which damaged cholangiocytes trigger a proinflammatory and profibrotic reaction. The nuclear vitamin D receptor (VDR) is highly expressed in cholangiocytes and exerts immune-regulatory functions in these cells. In the present study, we examined the protective function of VDR and other vitamin D signaling pathways in chronic cholangiopathy and cholangiocytes.

Methods: Vdr and Abcb4 double knockout mice were compared to the Abcb4 single knockout, and associated with an overexpression of proinflammatory factors. The proinflammatory phenotype of cholangiocytes was also exacerbated following VDR silencing in vitro. The expression of proinflammatory factors and the severity of cholangiopathy were reduced in the double knockout mice treated with the vitamin D analog calcipotriol or with vitamin D. In vitro, the inflammatory response to TNFα was significantly reduced by calcipotriol in biliary cells silenced for VDR, and this effect was abolished by co-silencing the plasma membrane receptor of vitamin D, protein disulfide-isomerase A3 (PDIA3).

1. Introduction

Cholangiopathies are chronic liver diseases in which damaged cholangiocytes trigger a proinflammatory and profibrotic response, that leads to the development of cirrhosis and end-stage liver disease [1]. Vitamin D deficiency is common in chronic liver diseases, and it is associated with increased liver inflammation and fibrosis [2-5]. It has also been reported that vitamin D deficiency is associated with an aggravation of liver fibrosis in a model of chronic cholangiopathy [6] that mimics primary sclerosing cholangitis (PSC), i.e., the ATP-binding cassette transporter B4 (Abcb4) knockout mouse model [7-10].

Currently there are two vitamin D receptors described to mediate the biological effects of vitamin D. The nuclear receptor, vitamin D receptor (VDR), is the best characterized of these receptors. A membrane-associated receptor of vitamin D, protein disulfide-isomerase A3 (PDIA3) also known as endoplasmic reticulum protein 57 (ERP57), has also been described [11]. While PDIA3 elicits non-genomic responses, VDR mediates the biological effects of vitamin D by modulating the transcription of target genes. Especially, VDR mediates anti-inflammatory and anti-fibrotic effects of vitamin D through gene regulation. Of particular interest with respect to cholangiopathies, VDR expression is restricted to non-parenchymal cells in the liver, and largely predominant in cholangiocytes [12,13], implying direct actions of VDR in cholangiocytes and cholangiopathies. Furthermore, VDR gene variations have been associated with auto-immune biliary diseases [14]. We also showed that VDR expression in cholangiocytes was increased in the Abcb4 knockout mice [13], suggesting an activation of VDR signaling in a chronic setting of cholangiopathy. Moreover, other ligands such as bile acids may account for VDR protective effects in the liver [15].

In the present study we tested the protective function of VDR in chronic cholangiopathy by inactivating VDR in the Abcb4 knockout mouse model and we also evaluated the potential of vitamin D and vitamin D analog to exert VDR-independent effects in this model and in cholangiocyte cell models.

2. Materials and methods

2.1. Animal experiments

Abcb4 simple knockout mice and their wildtype littermates were bred, using Abcb4+/− heterozygous mice on an FVB/N genetic background (FVB.129P2-Abcb4tm1Bor/J) provided by Sanofi R&D (Chilly-Mazarin, France). To develop Vdr/Abcb4 double knockout congenic mice, first we generated Vdr-/− mice on an FVB/N background. Vdr+/− mice on a C57BL/6J background (B6.129S4-Vdr<sup>tm1Bor</sup>/J) from Charles River Laboratories (Wilmington, MA, USA), were backcrossed with wildtype FVB/N mice (Charles River Laboratories) for 5 generations, using a speed congenics protocol. Next, Vdr+/− and Abcb4+/− mice on a FVB/N background were crossed to generate Vdr+/−/Abcb4+/− mice, which were further crossed to obtain Vdr+/−/Abcb4+/− and Vdr+/−/Abcb4−/− mice (Supplementary Fig. S1A-B). Wildtype mice used as a reference in the study, were all on a FVB/N background. Mice were housed at CRSA animal facility (Institutional Animal Care and Use Direction, DDPP agreement No. C 75–12-01), in a temperature-controlled, specific pathogen-free environment, on a 12-hour light-dark cycle, with free access to a standard chow containing 1.2 IU vitamin D/kg (LASQdiet® Rod16-R, Genobios, Laval, France) and water. All investigations were performed in males. During housing, animals were monitored daily for healthy status. Sub-groups of mice received intra-peritoneal injections of 40 µg/kg calcipotriol (Tocris, Bristol, UK), 3 times a week, an optimal dose to produce beneficial effects according to a previous report [17], from the age of 4 weeks to 8 weeks, or long-term vitamin D dietary supply, in which case, mice were fed a diet containing 2.2 IU vitamin D/kg, enriched in calcium and phosphate (TD96348, Envigo, Huntington, UK) [16] after weaning at 4 weeks, until the age of 12 months. Mice were included in lifespan studies or sacrificed under isoflurane anesthesia, at different time points. Upon sacrifice, blood was withdrawn from the vena cava and the liver and spleen were collected and weighed. Liver samples were harvested following recommendations from the International Primary Sclerosing Cholangitis Study Group (IPSCSG) [10]. In a sub-set of experiments, cholangiocytes and different liver cell types were isolated from 8-week-old mice, using an in situ perfusion-based protocol, as previously described [13]. All experiments complied with the European Directive 2010/63/UE and the ARRIVE Guidelines, and were approved by the Ethics Committee of Animal Experiments, Charles Darwin No.5 (No. APAFI#364-2015032410575237v3 and APAFI#16333-2018072719352187v1).

2.2. Biochemistry

The concentrations of aspartate and alanine aminotransferases, alkaline phosphatase (ALP), total bilirubin, calcium and phosphate in plasma, were measured on an Olympus AU400 Analyzer. Bile acid concentrations in plasma were determined using the Bile Acid Kit Eco-line S+ (DiaSys Diagnostic Systems GmbH, Holzheim, Germany) on a Hitachi917 analyzer. Hydroxyproline content in liver tissue was measured in lobe 3, using a colorimetric kit from Sigma-Aldrich (Saint-Louis, MO, USA), as previously described [18].

2.3. Histology and (immuno)histochemistry

Formalin (4%)-fixed, paraffin-embedded, mouse and human liver tissue samples were cut into 4-µm-thick sections. Mouse liver tissue sections were stained with hematoxylin and eosin or Sirius red, or were immunostained for cytokeratin 19 (CK19) or F4/80, using an anti-CK19 antibody (TROMA III, Developmental Studies Hybridoma Bank, Iowa University, IA, USA), and an anti-F4/80 antibody (SP115, Abcam, Cambridge, UK), respectively, as described [19,20]. Stained sections were scanned on a virtual slide scanner (Hamamatsu, Tokyo, Japan) 2.0 HT, using a 3-charge-coupled device, time-delay integration camera with a resolution of 1.84 µm/pixel (x20 objective) and 0.92 µm/pixel (x40 objective). Morphometric analyses were performed blinded, using ImageJ analysis software (National Institutes of Health, Bethesda, MD, USA). Paraffin-embedded human liver samples stored in the Pathological Department of Saint-Antoine Hospital were provided by this Department. Normal liver sample was from a patient who underwent liver surgery for tumor and pathological liver from a patient with PSC who underwent liver surgery for gallbladder carcinoma. Human liver tissue sections were immunolabeled for PDIA3. First, they were incubated in sodium citrate pH 6, for 20 min at 95 °C, to unmask epitopes, and then with 3% bovine serum albumin, to block unspecific binding. Thereafter, sections were incubated with PDIA3 antibody (CL2444, Sigma-Aldrich) diluted 1/100 in Envision flex diluent (Agilent Technologies, Santa Clara, CA, USA), overnight at 4 °C. Sections were then incubated with a secondary anti-mouse antibody coupled to Alexa fluor
488 (Invitrogen/Thermo Fisher Scientific, Waltham, MA, USA) diluted 1/200 in 3% bovine serum albumin, at room temperature for 1 h. Nuclear staining was performed, using DRAQ5 (Abcam) at 1/1000, for 5 min at room temperature. Tissue sections were examined with a SP2 confocal microscope (Leica, Bannockburn, IL, USA).

2.4. In vitro studies

The human biliary epithelial cells Mz-ChA-1 and EGI-1 were obtained from Dr. A. Knuth (Zurich University, Switzerland) and from the German Collection of Microorganisms and Cell Cultures (DSMZ, Braunschweig, Germany), respectively. Although derived from tumor cells, these cell lines can be phenotypically similar to primary biliary epithelial cells [21], and have been validated as surrogate models of epithelial cells [21]. Confocal microscopic images were captured with a Leica SP2 confocal microscope (Leica, Bannockburn, IL, USA).

2.6. Immunoblot

Proteins were extracted from liver or colon tissue, separated by 10% SDS-PAGE and transferred to nitrocellulose membranes. Membranes were incubated with primary antibodies raised against PDE1A (1/2000; ab10287 Abcam), VDR (1/200; sc-13133 Santa Cruz, Dallas, TX, USA), amphotericin B (Thermo Fisher Scientific). For transient transfection experiments, Mz-ChA-1 and EGI-1 cells were seeded into 6-well plates (250,000 and 140,000 cells/well, respectively). Cells were transfected with ON-TARGETplus human VDR or PDIA3 siRNA SMARTpools, or siGENOME Non-Targeting siRNA (Horizon Discovery Ltd., Cambridge, UK) using DharmaFECT 4 (Horizon Discovery LTD). Seventy-two hours after transfection, cells were incubated with serum-free medium for 12 h and then treated with tumor necrosis factor (TNF) (10 ng/mL; Sigma-Aldrich), as previously described [25, 26], combined with calcipotriol (0.1 μg/mL). Clear staining was performed, using DRAQ5 (Abcam) at 1/1000, for 5 min at room temperature. Tissue sections were examined with a SP2 confocal microscope (Leica, Bannockburn, IL, USA).

2.5. Reverse transcription quantitative PCR (RT-qPCR)

Total RNA was extracted using RNeasy columns (Qiagen, Courtaboeuf, France). Complementary DNA was synthesized from total RNA (1 μg), using the SuperScript II Reverse Transcriptase (Thermo Fisher Scientific), and qPCR was performed using the Sybr Green Master Mix, on a Light-Cycler 96 (Roche Diagnostics, Basel, Switzerland). Primer sequences are provided in Supplementary Table S1. The mRNA levels of target genes were normalized to those of hypoxanthine phosphoribosyltransferase 1 (Hprt1) in mouse or glyceraldehyde 3-phosphate dehydrogenase (GAPDH) in human, and expressed as relative levels (2^{-ΔΔCT}).

2.6. Immunoblot

Proteins were extracted from liver or colon tissue, separated by 10% SDS-PAGE and transferred to nitrocellulose membranes. Membranes were incubated with primary antibodies raised against PDE1A (1/2000; ab10287 Abcam), VDR (1/200; sc-13133 Santa Cruz, Dallas, TX, USA), amphotericin B (Thermo Fisher Scientific). For transient transfection experiments, Mz-ChA-1 and EGI-1 cells were seeded into 6-well plates (250,000 and 140,000 cells/well, respectively). Cells were transfected with ON-TARGETplus human VDR or PDIA3 siRNA SMARTpools, or siGENOME Non-Targeting siRNA (Horizon Discovery Ltd., Cambridge, UK) using DharmaFECT 4 (Horizon Discovery LTD). Seventy-two hours after transfection, cells were incubated with serum-free medium for 12 h and then treated with tumor necrosis factor (TNF) (10 ng/mL; Sigma-Aldrich), as previously described [25, 26], combined with calcipotriol (100 nmol/L) [27] or vehicle (DMSO) for 24 h. Cell lines were routinely screened for the presence of mycoplasma and authenticated for polymorphic markers to prevent cross-contamination.

3. Results

3.1. VDR ablation causes a reduction of lifespan and an increase in the severity of liver injury in Abcb4 knockout mice

Double knockout (Vdr−/−;Abcb4−/−) mice were generated and monitored in comparison with simple knockout (Vdr−/−;Abcb4−/+ or Vdr−/+;Abcb4−/−) littermates, for up to 12 months. Vdr−/−;Abcb4−/− mice were viable and showed no overt phenotypic difference with Vdr−/−;Abcb4−/− littermates at birth. During follow-up, they showed moderate hypocalcemia compared to Vdr−/−;Abcb4−−, whereas the plasma concentrations of phosphate, although transiently lower than in the Vdr−/−;Abcb4−/− mice, remained above normal levels (Supplementary Fig. S1C-D). Noticeably, lifespan was significantly reduced in Vdr−/−;Abcb4−/− mice as compared to Vdr−/−;Abcb4−/− mice, and did not exceed 11 months in these animals (Fig. 1A).

To evaluate the impact of Vdr inhibition on liver phenotype in Abcb4−/− mice, we performed comparative analyses of liver disease features in Vdr−/−;Abcb4−/− and Vdr−/−;Abcb4−/− mice at the age of 2 weeks, 4 weeks, 8 weeks and 6 months. Macroscopic examination showed that, compared to simple knockout mice, Vdr−/−;Abcb4−/− mice developed more severe hepaticomegaly and splenomegaly (Fig. 1B). Histological analysis was performed using an adaptation (described in Supplementary Materials and Methods) of Nakamura scoring [28]. According to this analysis, cholangitis and fibrosis appeared to be more pronounced in Vdr−/−;Abcb4−/− mice than in age-matched Vdr−/−/− mice between 4 weeks and 6 months. The plasma levels of alanine aminotransferase (ALT) (not shown) and aspartate aminotransferase (AST), which from 4 weeks on, were 1.5 to 2.5 higher than those observed in Vdr−/−/−;Abcb4−/− mice (Fig. 1D). The plasma levels of ALP also rose to a greater extent in Vdr−/−/−;Abcb4−/− mice than in Vdr−/−/−;Abcb4−/− mice from 4 weeks on, as did those of total bilirubin and bile acids from 8 weeks on (Fig. 1D). Taken together these results indicated that Vdr−/−/−;Abcb4−/− mice developed more severe cholestatic liver injury than Vdr−/−/−;Abcb4−/− mice.

3.2. VDR ablation causes an aggravation of cholangiopathy features in Abcb4 knockout mice

Ductular reaction, which is characterized by a proliferative response of cholangiocytes to injury, is a hallmark of cholangiopathies. We performed CK19 immunostaining on liver tissue sections to assess ductular reaction in the simple and double knockout mice. As previously reported in the Abcb4 simple knockout mice [29], ductular reaction reached its maximal point both in Vdr−/−;Abcb4−/− and Vdr−/−;Abcb4−/− mice at the age of 8 weeks, and became less prominent from this point on (Fig. 2A). Both at 8 weeks and 6 months, the ductular reaction was significantly more pronounced in Vdr−/−;Abcb4−/− mice than in Vdr−/−/−;Abcb4−/− mice (Fig. 2A). Thus, reactive cholangiocytes were more abundant in Vdr−/−;Abcb4−/− mice than in Vdr−/−/−;Abcb4−/− mice.

Reactive cholangiocytes contribute to liver inflammation in cholangiopathies by releasing pro-inflammatory mediators. Therefore, we next assessed the expression of pro-inflammatory factors that are typically produced by reactive cholangiocytes in cholangiopathies in both groups of mice. At the peak time of ductular reaction, i.e., 8 weeks, pro-inflammatory factors including Tnfα, vascular cell adhesion molecule 1 (VCAM1), C-C motif chemokine ligand (Ccl)2, Ccl20, S100a8, S100a9 and matrix metalloproteinase 9 (Mmp9) were overexpressed in the liver of
Fig. 1. VDR ablation has a deleterious impact on the phenotype of Abcb4 knockout mice. Vdr⁻/⁻;Abcb4⁻/⁻ compared to Vdr⁺/⁺;Abcb4⁺/⁺ mice showed (A) a reduction of survival estimated by the Kaplan-Meier method (n = 15 mice per group) and (B-D) more severe course of liver disease, as indicated by analyses at different time points of (B) liver weight and spleen weight to body weight ratios (n = 8-14 mice per group); (C) hematoxylin and eosin-stained liver tissue sections (arrowheads point to onion-skin type fibrosis and fibrotic septa) and (D) plasma concentrations of aspartate aminotransferase (AST), alkaline phosphatase (ALP), total bilirubin and bile acids (n = 5-10 mice per group). Bar graphs represent means ± SD; dashed lines represent the mean values in n = 6 (8 weeks old) wildtype (WT) mice; *P < 0.05; **P < 0.01; ***P < 0.001; ****P < 0.0001 (Log-rank test for A; Mann-Whitney U test for B and D). Scale bars = 500 μm.
Fig. 2. VDR ablation aggravates cholangiopathy features in Abcb4 knockout mice.

Vdr−/−Abcb4−/− compared to Vdr+/+Abcb4−/− mice showed more severe cholangiopathy as indicated by analyses at different time points of (A) ductular reaction assessed by cytokeratin 19 (CK19) immunostaining (n = 6–7 mice per group), (B-C) hepatic inflammation assessed by (B) RT-qPCR of tumor necrosis factor α (Tnfα), vascular cell adhesion molecule 1 (Vcam1), C-C motif chemokine ligand (Ccl) 2, Ccl20, S100a8, S100a9, matrix metalloproteinase 9 (Mmp9) (n = 6–9 mice per group), expressed relative to a pool of hepatic mRNA from n = 8 (8 weeks old) wildtype (WT) mice and (C) F4/80 immunostaining of macrophages (n = 6–7 mice per group), and (D) liver fibrosis assessed by Sirius red staining and hydroxyproline content (n = 7–8 mice per group). Bar graphs represent means ± SD; dashed lines represent the mean values in n = 6 (8 weeks old) WT mice; *p < 0.05; **p < 0.01; ***p < 0.001 (Mann-Whitney U test). Scale bars = 250 μm in A and C, and 500 μm in D.
both Vdr+/-;Abcb4 +/- and Vdr-/-;Abcb4 +/- mice, as shown relative to wildtype mice. Importantly, all these genes were expressed at higher levels in Vdr/-; Abcb4 +/- mice than in Vdr+/-; Abcb4 +/- mice (Fig. 2B). The overexpression of Ccl2 and Ccl20, which play an essential role in the recruitment of circulating monocytes to injured tissues, was accompanied by an overexpression of their receptors, i.e., CC chemokine receptor (Ccr)2 and Ccr6, respectively (Supplementary Fig. S2). Consistent with these results, macrophages were more abundant in the liver of Vdr/-; Abcb4 +/- mice than in Vdr+/-; Abcb4 +/- mice, as ascertained by F4/80 immunostaining (Fig. 2C). Altogether these results attested an exacerbation of the immune response in the liver of Abcb4 +/- mice in the absence of VDR.

Proinflammatory chemokines and cytokines overproduced in the liver are expected to stimulate liver myofibroblasts and promote liver fibrosis. The quantification of hepatic hydroxyproline content indicated that more collagen accumulated in the liver of Vdr/-; Abcb4 +/- mice compared to single knockout mice (Fig. 2D, right lower panel). In line with this observation, Sirius red staining showed more extensive liver fibrosis in Vdr/-; Abcb4 +/- mice than in Vdr+/-; Abcb4 +/- mice (Fig. 2D, upper, and left lower panels). In agreement with a previous report [30], we observed a stabilization of the liver phenotype in the Abcb4 +/- mice (on FVB/N background) with no further aggravation after 8 weeks, and this was true irrespective of the VDR status.

Collectively, these findings indicate that in the absence of VDR, ductular reaction, pro-inflammatory signals and collagen deposition were amplified in the liver of Abcb4 +/- mice, highlighting a protective action of VDR in the setting of chronic cholangiopathy.

3.3. Calcipotriol treatment reverses the aggravation of cholangiopathy features in Vdr-/-; Abcb4 +/- mice

To gain further insights into the protection that vitamin D signaling might confer in the setting of cholangiopathies, we administered a 4-week treatment with calcipotriol, a synthetic vitamin D analog, both in Vdr+/-; Abcb4 +/- and Vdr-/-; Abcb4 +/- mice. At the end of treatment, no significant change in blood tests of cholestatic liver injury was observed either in Vdr+/-; Abcb4 +/- or Vdr-/-; Abcb4 +/- mice. However, the ductular reaction assessed by CK19 immunostaining was significantly reduced following calcipotriol treatment in Vdr-/-; Abcb4 +/- mice, whereas it remained unchanged in the Vdr+/-; Abcb4 +/- mice (Fig. 3B). Calcipotriol treatment also elicited a significant decrease in the expression of Trfha, Ccl2, Ccl20, S100a8, S100a9 and Mmp9 in the liver of Vdr-/-; Abcb4 +/- mice while no effect on the expression of these factors was found in the liver of Vdr+/-; Abcb4 +/- mice (Fig. 3C). Accordingly, the inflammatory infiltrate assessed by F4/80 immunostaining was reduced in calcipotriol-treated Vdr-/-; Abcb4 +/- mice compared to the untreated mice (Fig. 3D), and fibrosis less severe as shown by a significant difference in hydroxyproline content (Fig. 3E). By contrast, calcipotriol treatment had no such effects in Vdr+/-; Abcb4 +/- mice (Fig. 3D). Overall, while calcipotriol treatment did not stop the progression of liver disease in Vdr-/-; Abcb4 +/- mice, it improved liver status and reversed the aggravation of cholangiopathy features in Vdr-/-; Abcb4 +/- mice. This indicated that the vitamin D analog activated a VDR-independent pathway that attenuated the severity of cholangiopathy in the double knockout mice.

3.4. Pdia3 is overexpressed in the liver and cholangiocytes of Vdr-/-; Abcb4 +/- mice

Pdia3, the membrane receptor of vitamin D, mediates anti-inflammatory actions by mechanisms such as the ectodomain shedding of TNF receptor 1 [31,32]. We hypothesized that the VDR-independent effects of calcipotriol observed in Vdr-/-; Abcb4 +/- mice, could be mediated by Pdia3. Consistent with this hypothesis, we found that hepatic Pdia3 mRNA and protein expression was significantly increased in Vdr-/-; Abcb4 +/- mice compared to wildtype (FVB/N) and Vdr+/-; Abcb4 +/- mice (Fig. 4A and B). Looking into pools of individual liver cell types that were isolated from wildtype and simple Abcb4 knockout mice, we found that they all expressed Pdia3, but that Pdia3 expression increased distinctively in cholangiocytes from Abcb4 knockout mice compared to wildtype, whereas little change occurred in the other cell types (Fig. 4C). We also examined Pdia3 expression specifically in cholangiocytes from Vdr-/-; Abcb4 +/- mice, and found an even higher expression than in the simple knockout and wildtype mice (Fig. 4D). Because cholangiocytes i) are more numerous and ii) express more Pdia3 in the liver of Vdr-/-; Abcb4 +/- mice than in the wildtype and simple Abcb4 knockout mice, we inferred that they accounted at least partly for Pdia3 overexpression in the liver of the double knockout. We could also show that in the liver tissue from a patient with PSC, Pdia3 was immunodetected in cholangiocytes of both small and large bile ducts and localized at their plasma membrane where it could mediate vitamin D effects (Fig. 4E). Moreover, the intensity of labeling in cholangiocytes appeared to be higher in PSC than in normal liver (Fig. 4E). Collectively, our results indicated that cholangiocytes are a major site of Pdia3 expression in cholangiopathy.

3.5. Pdia3 mediates VDR-independent anti-inflammatory effects of calcipotriol in cholangiocytes

To examine whether Pdia3 in cholangiocytes could contribute to VDR-independent effects of calcipotriol in Vdr-/-; Abcb4 +/- mice, we invalidated VDR and Pdia3 in human cholangiocytes. Two human biliary epithelial cell lines, Mz-Cha-1 and EGI-1, commonly studied as surrogate models of non-tumoral human cholangiocytes [15,16,21–24], were transfected with VDR ± Pdia3 siRNA (Supplementary Fig. S3A and B). VDR knockdown caused a significant increase in the expression of pro-inflammatory factors that were found to be overexpressed in the liver of Vdr-/-; Abcb4 +/- mice, including Ccl2, Ccl20, S100a9 and Mmp9 in MzCha-1 cells (Fig. 5A), and Ccl20, S100a9 and Mmp9 in EGI-1 (Supplementary Fig. S4A). Similar variations of these factors were observed in cholangiocytes isolated from the double compared to simple knockout mice, even though only the difference in Ccl20 expression reached statistical significance (Supplementary Fig. S5). VDR knockdown also caused a significant increase in Pdia3 in human biliary epithelial cell lines (Supplementary Fig. S3A and B). Next, we tested the effect of calcipotriol in the context of cholangiocyte inflammatory response to TNFα [25,26]. TNFα induced a marked increase in the expression of CCL2, CCL20, S100A9 and MMP9 in Mz-Cha-1 cells (Fig. 5B). Calcipotriol significantly reduced the rise triggered by TNFα in the expression of CCL2, CCL20 and MMP9 in these cells (Fig. 5B). The inhibitory effect of calcipotriol was also observed in the cells silenced for VDR, whereas no such effect occurred in the cells silenced for both VDR and Pdia3 (Fig. 5B). EGI-1 cells also displayed an overexpression of CCL20, S100A9 and MMP9, when silenced for VDR (Supplementary Fig. S4A). Although they were poorly responsive to TNFα in basal conditions, the overexpression of S100A9 and MMP9 induced by TNFα was reduced by calcipotriol in cells lacking VDR, but not in those lacking both VDR and Pdia3 (Supplementary Fig. S4B). Taken together, these results indicated that in the absence of VDR, Pdia3 mediated anti-inflammatory effects of calcipotriol in the liver, which may have contributed to the protective effects of calcipotriol observed in Vdr-/-; Abcb4 +/- mice.

3.6. Long-term vitamin D supplementation alleviates the severity of cholangiopathy phenotype in Vdr-/-; Abcb4 +/- mice

To further confirm that vitamin D can elicit VDR-independent protective mechanisms in cholangiopathy, we tested long-term natural vitamin D supplementation in the Abcb4 knockout mice. Vdr-/-; Abcb4 +/- and Vdr+/-; Abcb4 +/- mice were fed a vitamin D-enriched diet from weaning until the age of 6 months. Akin to short-term pharmacological treatment with calcipotriol, long-term vitamin D supplementation
E. Gonzalez-Sanchez et al.
improved cholangiopathy features in Vdr-invalided Abcb4 knockout mice. Cholestasis, ductular reaction and liver fibrosis were all significantly less intense in the double knockout mice who received vitamin D supplementation for 6 months compared to those who were fed a regular chow diet (Fig. 6A-C). By contrast, no improvement resulted from vitamin D supplementation in the Vdr+/−/Abcb4−/− mice even though we observed a significant reduction of ALP levels which might reflect an improvement by vitamin D supplementation of the hepatic osteodystrophy that occurs in Abcb4−/− mice [33].

Consistent with these results, long-term vitamin D supplementation improved survival rates only in Vdr+/−/Abcb4−/− mice (Fig. 6D). These results confirmed the existence of an alternative vitamin D signaling pathway independent of VDR, which promotes protective mechanisms in cholangiopathy.

4. Discussion

In this study, we demonstrate the protective functions of VDR in a mouse model of chronic cholangiopathy. Cholestasis, hepatic inflammation and fibrosis were exacerbated by the loss of VDR in Abcb4 knockout mice. Yet, the activation of VDR by vitamin D or calcipotriol treatments failed to ameliorate cholangiopathy in Abcb4 knockout mice. Instead, vitamin D and calcipotriol treatments improved liver injury in the Abcb4 knockout mice that lacked VDR, implying the existence of VDR-independent protective effects of vitamin D and analog in this model. Our data provide evidence to indicate that VDR-independent actions of vitamin D in this context may be mediated by PDI3.

Biochemical markers of liver injury and inflammation were increased in Abcb4 knockout mice in the absence of VDR. Vdr knockout mice on a C57Bl/6J background spontaneously develop hepatic inflammation and fibrosis at the age of 6 months [27,34]. These observations have been attributed to anti-inflammatory and anti-fibrotic effects of VDR in liver macrophages [34] and hepatic stellate cells [27], respectively. Without excluding that these effects contributed to the development of a more severe liver phenotype in Vdr−/−/Abcb4−/− mice compared to Vdr+/−/Abcb4−/−, we herein specifically addressed the contribution of Vdr loss in cholangiocytes. The first reason is that VDR expression in the liver, is most prominent in cholangiocytes than in any other liver cell type, both in humans [15] and in mice, especially in the context of chronic cholangiopathy, as shown in Abcb4 knockout mice [13]. The second reason is that cholangiocytes are proliferative and produce pro-inflammatory factors in cholangiopathies, whereby they promote fibrosis and disease progression in these disorders [1]. We found that cholangiocytes lacking VDR overexpressed pro-inflammatory factors both in vivo and in vitro. Moreover, cholangiocytes lacking VDR were more proliferative in vivo (Fig. 2A), suggesting that cholangiocytes played a significant role in the aggravation of cholangiopathy caused by VDR loss. While VDR has been shown to promote epithelial barrier integrity [16,35], we could not detect more bile duct disruption in Vdr−/− mice than in Vdr+/− mice in the chronic model of Abcb4 invalidation (Supplementary Fig. S6). Neither did we detect a significant increase in the permeability or histology of the intestine of Vdr−/−/Abcb4−/− compared to Vdr+/−/Abcb4−/− mice (Supplementary Fig. S7).

Activation of VDR by vitamin D analogs has been considered as a therapeutic option in chronic liver diseases. Supporting this strategy, hypocalcemic vitamin D analogs approved for use in patients (i.e. calcipotriol, for topical treatments; alfalcacidol and paricalcitol for systemic treatments), have demonstrated antifibrotic properties both in hepatic stellate cells in vitro [27,36], and in mouse models of CCL- and thiacetamide-induced liver fibrosis in vivo [27,36,37]. Calcipotriol used as a prophylactic treatment has also been shown to prevent biliary fibrosis induced by bile duct ligation or 3,5-diethoxycarbonyl-1,4-dihydrocollidine (DDC) in mice [38]. However, when used as a curative treatment, calcipotriol herein failed to improve liver fibrosis in Abcb4 knockout mice. Liver fibrosis in Abcb4 knockout mice was left unchanged by treatments with active vitamin D (calcitriol), or a high-dose vitamin D diet, as shown here and in a previous study [6,39]. Yet, Abcb4 knockout mice on low vitamin D diet display aggravated liver fibrosis, which in this particular case, can be ameliorated by a vitamin D-sufficient diet [6]. Importantly, in such case, a high vitamin D supplementation adds no benefit over a normal intake [6]. Taken together, these data indicate that normal levels of vitamin D are sufficient to ensure VDR-dependent protective mechanisms in cholangiopathies. They suggest that in a setting of effective VDR signaling, increasing VDR ligands does not provide further therapeutic benefit.

Remarkably, we found that both high-dose vitamin D supplementation and a vitamin D analog were beneficial in Abcb4 knockout mice lacking VDR, highlighting VDR-independent protective effects of vitamin D. We postulated that VDR-independent protective effects of vitamin D and analogs in the liver, could be mediated by PDI3, the membrane receptor of vitamin D [11]. Consistent with this assumption, we could show that PDI3 was expressed at high levels in cholangiocytes of Abcb4 knockout mice. Furthermore, pro-inflammatory response was suppressed by calcipotriol acting via PDI3 in cholangiocytes, as demonstrated in vitro. In keeping with this result, PDI3 was previously shown to mediate nongenomic actions of vitamin D by shedding the ectodomain of TNF receptor 1, thus decreasing responsiveness to TNFα [31]. Noteworthily, this mechanism is activated by Vitamin D3 and derivatives [32], to which calcipotriol belongs. The binding potency of vitamin D for PDI3 is lower than for VDR [40], suggesting that vitamin D or calcipotriol preferentially bind to VDR in cells that express both receptors. Therefore, we suggest that PDI3 mediates anti-inflammatory effects of vitamin D particularly in the context of defective VDR signaling, when the ligand bioavailability is increased and PDI3 overexpressed, as shown here and in a previous study [41]. Nevertheless, specific ligands of this receptor are currently lacking and need to be developed to further explore the role of PDI3 in the inflammatory response of cholangiocytes.

The clinical relevance of our finding is supported by previous studies showing that in subjects with liver disease, VDR gene variants can lead to low VDR expression in the liver, which is associated with a higher severity of inflammation and fibrosis [42,43]. Therefore, while a treatment aimed to maintain normal levels of vitamin D may be sufficient in a large number of patients with cholangiopathies, a subset of patients could benefit from vitamin D treatments via PDI3. Further studies are needed to determine the impact of VDR polymorphisms on disease progression (prognosis, severity or risk of cancer development) in patients with cholangiopathies. This may help to identify subgroup of patients that would benefit from treatments with supra-physiological doses of vitamin D. Furthermore, additional strategies aimed to boost PDI3 anti-inflammatory effects with PDI3-specific ligands may be of clinical interest regardless of VDR expression status. The present study
Fig. 4. Protein disulfide-isomerase A3 (PDIA3) is overexpressed in the liver and cholangiocytes of Abcb4 knockout mice lacking VDR. PDIA3 expression was analyzed in (A-D) 8 weeks old mice (A-B) whole liver from \( n = 6-9 \) per group by RT-qPCR and by immunoblot; (C) individual liver cell populations (\( n = 1 \) mRNA pool from 6 to 8 mice) by RT-qPCR; in A and C, results are expressed relative to a pool of hepatic mRNA from \( n = 8 \) wildtype (WT) mice; (D) in cholangiocytes (\( n = 3 \) different mRNA pools from 3 to 4 mice) by RT-qPCR (results are expressed relative to a pool of cholangiocyte mRNA from \( n = 8 \) WT mice; numbers within bars represent Ct values); (E) in tissue sections of normal human liver or liver from a patient with PSC; representative images highlight PDIA3 expression at the plasma membrane of cholangiocytes, both in small and large bile ducts (arrows and inset). Bar graphs represent means ± SD; * \( P < 0.05 \) (Kurskall-Wallis test followed by Dunn’s multiple comparison). Hep, hepatocytes; Chol, cholangiocytes; HSC, hepatic stellate cells; LSEC, liver sinusoidal endothelial cells; KC, Kupffer cells. Scale bars = 10 μm.
provides rationale to explore this strategy in the future.

In conclusion, the present findings provide new mechanistic insights into the involvement of vitamin D signaling in cholangiocytes and cholangiopathies. They indicate that the VDR status of patients with cholangiopathies may be as important as circulating vitamin D levels in these diseases. Moreover, our data provide evidence for PDIA3 anti-inflammatory effects in cholangiocytes, suggesting a potential interest as a therapeutic target in cholangiopathies.

Financial support
